

# An Introduction to Astronomical Telescopes

<http://www.bbc.co.uk/science/0/20937803>

This Power Point presentation was prepared in  
2017 for Delta Rehabilitation Center,  
Snohomish WA.

<http://www.deltafoundation.com/>

**Delta has a small observatory and a 10 inch Meade Cassegrain reflector telescope, which had the distinction of capturing Supernova 1999by in NGC 2841 during it's peak brightness. The Rochester Academy of Science website accepted this image into its data pool**

<http://www.deltafoundation.com/astronomy.htm>

**The First Telescope was invented by Galileo Galilei in 1609.  
It had a convex objective lens and a concave eyepiece  
in a long tube.**

A telescope with lenses is called  
A refracting telescope

<http://binoculars.net/does-refracting-telescope>

# 10 " Meade Cassegrain Reflecting Telescope

# Cassegrain Reflector

The Cassegrain scope reflects light back and forth in the telescope tube, allowing a much shorter telescope for its diameter.

[https://en.wikipedia.org/wiki/Cassegrain\\_reflector](https://en.wikipedia.org/wiki/Cassegrain_reflector)

# Martians?

# Typical Reflecting Telescope

Light from the object enters the tube, is reflected by a curved mirror back to a diagonal mirror where it reflected to the eyepiece.

<http://www.fortworthastro.com/beginner5.html>

# A parabolic mirror focuses light at a point

Reflecting telescopes use parabolic mirrors, which focus light at a point. Spherical mirrors focus light at different points along the axis of the telescope. The resulting distortion is called spherical aberration.

<http://www.astronomyasylum.com/telescopeoptictutorial.html>

# Atmospheric Distortion

Light in the atmosphere

Light hitting the ground-based telescope mirror

Resulting image

1 The uneven heating and cooling of the atmosphere creates moving bundles, or pockets, of air. These air pockets act like little lenses. The parallel light rays hit the bundles and bend in unpredictable ways.

2 The light rays bent by the atmosphere hit the mirror at different angles. The reflected rays cross at many shifting points, instead of at one focal point.

3 The result is a blurry, shifting image of the star.

Even with a parabolic mirror, optical telescopes still have a problem: atmospheric distortion, which causes stars to appear to twinkle

The largest optical telescopes are reflectors, and are usually on high mountains to reduce atmospheric distortion.

[https://en.wikipedia.org/wiki/List\\_of\\_largest\\_optical\\_reflecting\\_telescopes](https://en.wikipedia.org/wiki/List_of_largest_optical_reflecting_telescopes)

The twin Keck scopes on Maunakea in Hawaii are at 13,600 ft elevation

<http://hyperphysics.phy-astr.gsu.edu/hbase/Solar/palomar.html>

Large mirrors are difficult and expensive to produce and transport. The alternative is to build large mirrors in segments, which can be controlled by computerized adaptive optic systems, to form, in effect, a single large curved mirror. Above is model of Keck mirror

<http://astronomy.swin.edu.au/keck/>

# Looking down on the 36 Keck mirror segments

<http://www.astro.caltech.edu/research/keck/>

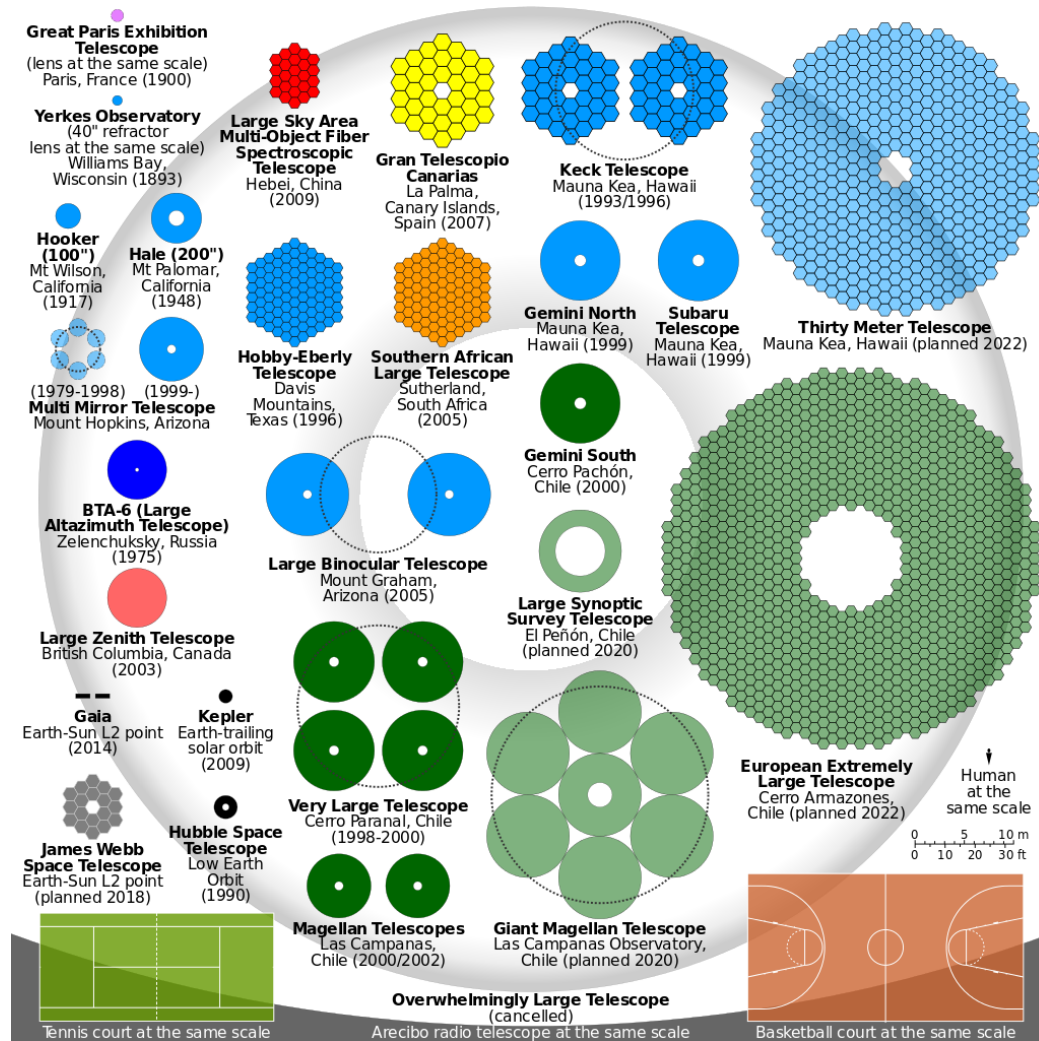

These adjustments also counter the effect of gravity as the telescope moves, as well as other environmental and structural effects that can affect the mirror shape.

# Primary mirrors of largest optical telescopes:

note the size of a human in lower right;  
note size of Keck mirrors in top row.

# Natural Guide Star AO

**Even on mountain tops, atmospheric distortion is significant.  
The solution again is Adaptive Optics.**

Light from a “guide” star near the telescope target falls on the adaptive optics system, where small sensors continuously monitor changes in the direction of light waves from the guide star. The sensors send this information to a computer, which controls the movements of actuators attached to the backs of the mirror segments.

<https://str.llnl.gov/str/Guidestr.htm>

<https://www.subarutelescope.org/Pressrelease/2006/11/20/index.html>

Since the guide star is very close to the telescope target, the corrections to the guide star image also correct the image of the telescope target.

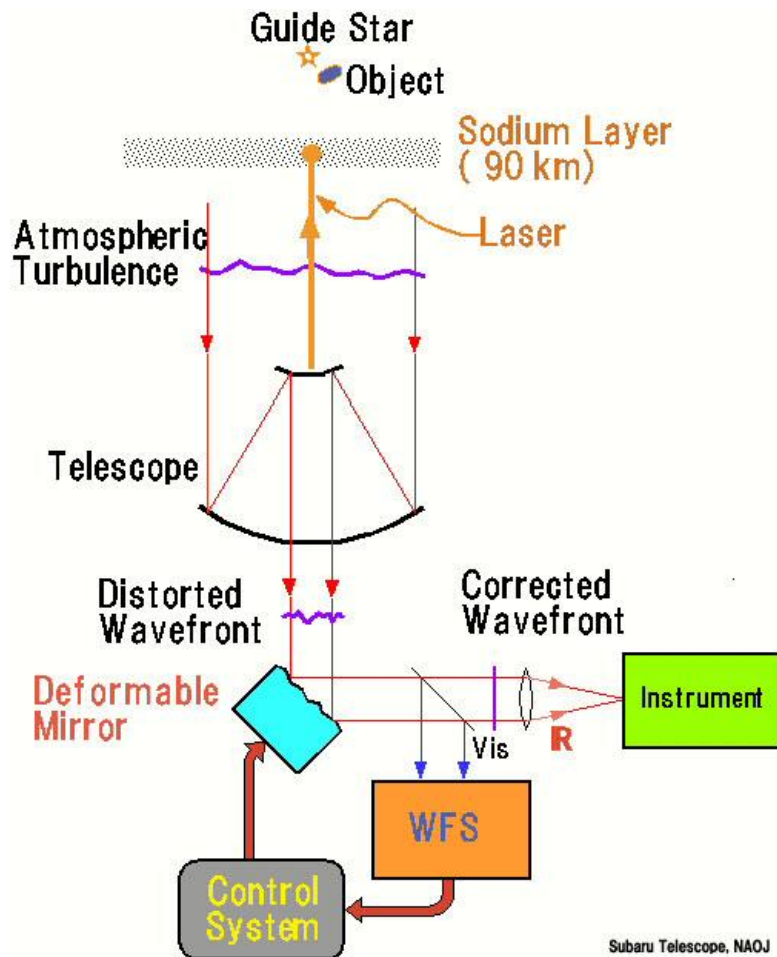

Without AO

With AO

# Laser Guide Star AO

Often there is no natural guide star near the object.

The solution is to create an artificial guide star using a laser to excite sodium atoms 60 miles above the earth. The sodium atoms are present in a thin shell around the earth, created by micrometeorites which vaporize as they enter the upper atmosphere.

The process of creating an artificial guide star is called “Laser Guide Star Adaptive Optics”

<https://str.llnl.gov/str/Guidestr.htm>

# Keck: Uranus without and with adaptive optics

<http://www.keckobservatory.org/support/ngao>

# Keck Adaptive Optics

# An electromagnetic wave

All of these optical telescopes work by getting light from the star or planet.  
A ray of light is an electromagnetic wave.

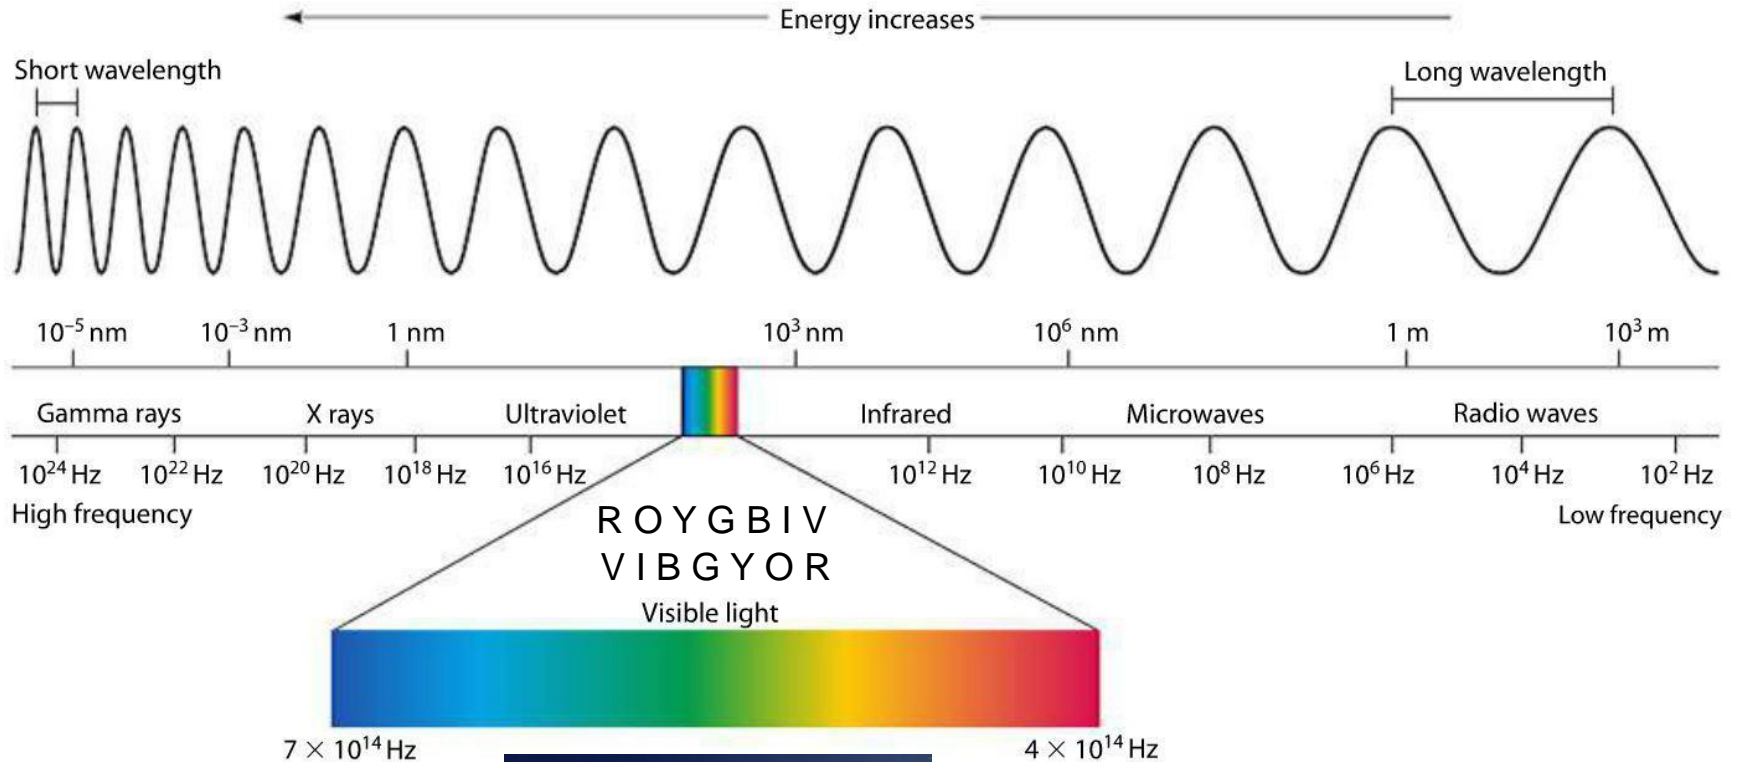

# Electromagnetic Spectrum

Electromagnetic waves include a whole spectrum of different wavelengths, from cosmic rays through visible light to microwaves, radio waves, and ELF waves

# Optical Scopes see light

Remember Keck and all other optical scopes work by getting light from the star or planet

# Radio scopes “see” radio waves

which are much longer and lower in frequency than light waves

Radio scopes can see through space dust and even cloudy skies; and it does not have to be dark

# Greenbank Radio Telescope West Virginia

<https://astronomynow.com/2015/03/31/race-to-detect-gravitational-waves-intensifies>

# Very Large Array Telescope, New Mexico

Radio waves from different radio scopes can also be added together by computers to get a better picture

This process is called Aperture synthesis, and produces images having the same angular resolution as an instrument the size of the entire collection.

[https://en.wikipedia.org/wiki/Aperture\\_synthesis](https://en.wikipedia.org/wiki/Aperture_synthesis)

The resolution however, depends on the number of telescopes in the array

# Observatories across the EM spectrum

[https://imagine.gsfc.nasa.gov/science/toolbox/emspectrum\\_observatories1.html](https://imagine.gsfc.nasa.gov/science/toolbox/emspectrum_observatories1.html)

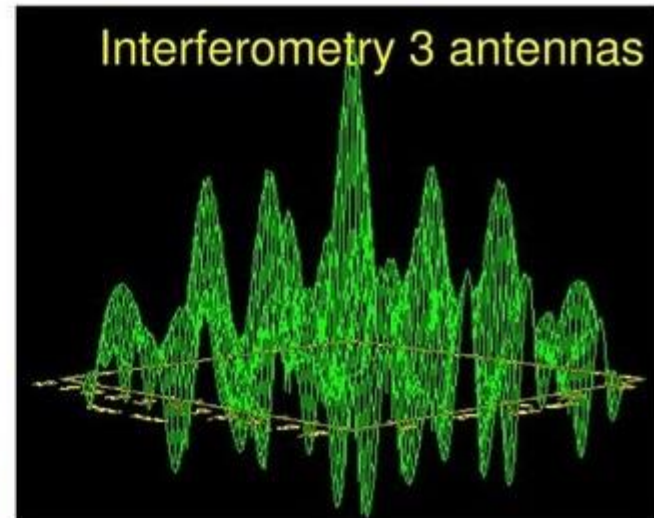

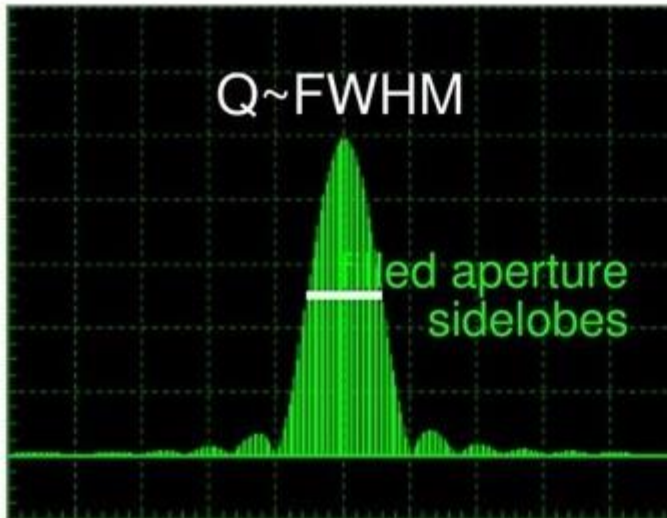

.One antenna: maximum resolution  $q \sim \lambda/D$   
-  $D$  25 m,  $\lambda$  21 cm ( $\nu$  1.4 GHz) gives  $q \sim 0.5^\circ$

.Many antennas:  
- Maximum resolution  $q \sim \lambda/B$   
-  $B \sim 200$  km at  $\lambda$  21 cm gives  $q \sim 0.2$  arcsec

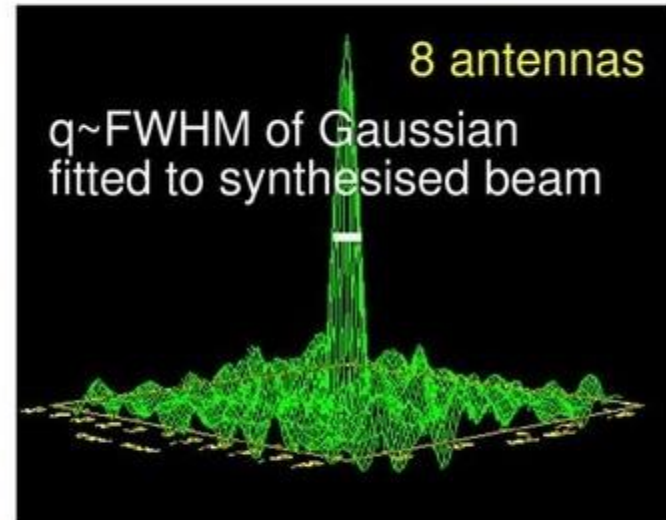

- One antenna: maximum resolution  $q \sim \lambda/D$ 
  - $D$  25 m,  $\lambda$  21 cm (n 1.4 GHz) gives  $q \sim 0.5^\circ$

- Many antennas:
  - Synthesised beam is Fourier transform of uv tracks
  - Gaps in uv coverage make sidelobes in beam

.One antenna: maximum resolution  $q \sim 1/D$   
-  $D$  25 m,  $l$  21 cm (n 1.4 GHz) gives  $q \sim 0.5^\circ$

.Many antennas:

- Maximum resolution  $q \sim 1/B$

- More antennas means fewer sidelobes
